DESCRIPTION

Uses of liquid biofuel in transport sector

Liquid biofuels are regarded an alternative fuel for all Internal Combustion (IC) engines that run on diesel, petrol or kerosene for use in land, air and marine transport vehicles. By 2030, it is estimated to supply around 10% of the transportation energy requirement, up from 5% in 2018. Liquid biofuel is used in a variety of applications, including ships and aviation, two of the most rapidly growing segments of the transportation industry. When compared to fossil fuel-derived engines, liquid biofuels created using sophisticated technology are employed to reduce pollution emissions in the atmosphere. Because advanced liquid biofuels have a high specific energy and are the only option for reducing CO₂, they are highly recommended for use in jet fuels.

Combining thermochemical and biological processes to obtain liquid biofuels from syngas is another intriguing possibility. This combined process involves the gasification of wastes into synthesis gas or syngas, followed by carboxydutrophic acetogenic bacteria (such as *Acetobacterium woodii*, *Butyribacterium methylotrophicum*, *Clostridium carboxidivorans*, *Eubacterium limosum*, *Moorella* and *Peptostreptococcus productus*) converting the gaseous carbon into organic acids (acetate, formate, butyrate). Microbiological processes involves the following advantages of low working temperature and pressure, high tolerance of hazardous gas compared to chemical catalysts, high substrate specificity and independence from the H₂:CO ratio.

Liquid biofuels have a number of appealing characteristics, including improved energy independence and lower greenhouse gas emissions. However, a variety of variables may limit the market adoption and supply of biofuels. The usage of alcohols and biodiesel in internal combustion engines is explored, as well as the technology of flexible-fuel cars. The use of iso-stoichiometric ternary blends of gasoline, ethanol and methanol as drop-in fuels for E85 flex-fuel vehicles is demonstrated. In this how biofuels can be integrated into a larger sustainable energy system for transportation based on carbon-neutral liquid fuels, Fermentation) are two methods for fermenting sugars. Separate

allowing for a steady evolution of vehicle and fuel technology. Diesel oil is replaced or supplemented with liquid biofuels. Bio components, such as bioethanol, bio methanol, esters, dimethyl ethers, pure vegetable oils and synthetic hydrocarbons, are rarely utilized in Poland, owing to the risk of freezing in tanks during the winter. As a liquid biofuel, unprocessed or purified oil extracted from the seeds of plants like rapeseed, soybean or sunflower was initially utilized. When the FAME (Fatty Acid Methyl Esters) extraction process became widespread, both plant and animal fatty acid methyl esters began to be employed as bio components in diesel oil or called biodiesel. FAME is made because the raw material from which they are made has a lower viscosity than the raw material from which they are made.

FAME is typically first-generation biofuels, while waste oils are increasingly being used. Despite this, the production of second generation biofuels from lignocellulosic biomass and third-generation biofuels from algae is quickly increasing. Owing to legislative reforms targeted at shifting away from the development of biofuels from food raw materials. The conversion of plant biomass to second generation biofuels is a multi-stage process. It all starts with proper plant material preparation (called effective pretreatment). Without a doubt; this is the most critical stage in the manufacture of second generation bioethanol. Since it affects the efficient use of the raw material. It entails mechanical, chemical and biological preparation of the raw material, which has a dense and complex structure.

Preparation of biofuels

Pretreatment involves grinding the raw material's solid phase, relaxing the lignocellulose's tight structure, breaking the crystalline structure of cellulose and separating lignin from cellulose. Because lignin does not yield bioethanol, it is an undesirable component. Then comes enzymatic hydrolysis of biomass, which is the process of breaking down polysaccharides into fermentable sugars (where the choice of effective enzyme preparations is critical), followed by ethanol fermentation (using appropriate microorganisms). SHF (Separate Hydrolysis and Fermentation) and SSF (Simultaneous Saccharification and

Hydrolysis and Fermentation is a two-step process that starts with hydrolysis and ends with ethanol fermentation. This allows for the modification of reaction conditions, but SSF is a faster and more efficient method that involves simultaneous hydrolysis and fermentation. This form of biofuel generation does not impair enzyme function, but it does necessitate the use of microorganisms that can withstand higher temperatures. Distillery yeast breaks down glucose into ethanol and carbon dioxide to produce biofuel (*Saccharomyces cerevisiae* L). However, distillation and dehydration are required before the ethanol may be employed in the transportation business. Without a doubt, using liquid biofuels instead of diesel and diesel would have a

lower environmental impact. However, liquid biofuels, like every other product, offer both advantages and disadvantages. The most significant of these are energy and cost consumption, as well as the necessity to use a large number of enzymes, the manufacturing and usage of which adds to the cost and financial burden on the environment. As a result, the development of advanced biofuels is still in its early stages, with the primary focus on improving production efficiency and lowering bioethanol production costs. The biggest drawback is the slow gas-to-liquid mass transfer rate, which necessitates particular reactor designs.
